

Below is one complete solution in JavaScript along with an explanation of the approach. You can use the following function as your implementation:

Js

Copy

```
function bigSorting(unsorted) {  
  // Sort the array using a custom comparator:  
  // 1. If two strings have different lengths, the one with fewer digits represents a smaller number.  
  // 2. If the strings have the same length, compare them lexicographically.  
  unsorted.sort((a, b) => {  
    if (a.length !== b.length) {  
      return a.length - b.length; // shorter string means smaller number  
    } else {  
      return a.localeCompare(b); // if same length, lexicographical comparison works  
    }  
  });  
  
  return unsorted;  
}
```

Explanation:

1. **Sorting by Length First:** Because each string represents a positive integer without leading zeros, a shorter string always indicates a smaller number.
2. **Lexicographical Comparison:** If two strings have the same length, their lexicographical order is the same as their numerical order. For instance, digit numbers like "150" and "200", comparing them as strings gives the correct result.
3. **Using a Custom Comparator:** The built-in `sort()` function is overridden with a custom comparator that implements the above logic. First, it compares string lengths; if they differ

This solution meets the constraints because it avoids converting the strings to numbers (which could be problematic for very large numbers) and
